Abstract

The paper presents a language model that develops syntactic structure and uses it to extract meaningful information from the word history, thus enabling the use of long distance dependencies. The model assigns probability to every joint sequence of words—binary-parse-structure with headword annotation. The model, its probabilistic parametrization, and a set of experiments meant to evaluate its predictive power are presented.

Figure 2: A word-parse k-prefix

1 Introduction

The main goal of the proposed project is to develop a language model(LM) that uses syntactic structure. The principles that guided this proposal were:

- the model will develop syntactic knowledge as a built-in feature; it will assign a probability to every joint sequence of words—binary-parse-structure;
- the model should operate in a left-to-right manner so that it would be possible to decode word lattices provided by an automatic speech recognizer.

The model consists of two modules: a next word *predictor* which makes use of syntactic structure as developed by a *parser*. The operations of these two modules are intertwined.

2 The Basic Idea and Terminology

Consider predicting the word **barked** in the sentence:

the dog I heard yesterday barked again.

A 3-gram approach would predict **barked** from (**heard**, **yesterday**) whereas it is clear that the predictor should use the word **dog** which is outside the reach of even 4-grams. Our assumption is that what enables us to make a good prediction of **barked** is the syntactic structure in the

past. The correct *partial parse* of the word history when predicting **barked** is shown in Figure 1. The word **dog** is called the *headword* of the *constituent* (**the** (**dog** (...))) and **dog** is an *exposed headword* when predicting **barked** — topmost headword in the largest constituent that contains it. The syntactic structure in the past filters out irrelevant words and points to the important ones, thus enabling the use of long distance information when predicting the next word. Our model will assign a probability $P(W, T)$ to every sentence W with every possible binary branching parse T and every possible headword annotation for every constituent of T . Let W be a sentence of length l words to which we have prepended $\langle s \rangle$ and appended $\langle /s \rangle$ so that $w_0 = \langle s \rangle$ and $w_{l+1} = \langle /s \rangle$. Let W_k be the word k-prefix $w_0 \dots w_k$ of the sentence and $W_k T_k$ the *word-parse k-prefix*. To stress this point, a word-parse k-prefix contains only those binary trees whose span is completely included in the word k-prefix, excluding $w_0 = \langle s \rangle$. Single words can be regarded as root-only trees. Figure 2 shows a word-parse k-prefix; $h_0 \dots h_{-m}$ are the *exposed headwords*. A *complete parse* — Figure 3 — is any binary parse of the $w_1 \dots w_l \langle /s \rangle$ sequence with the restriction that $\langle /s \rangle$ is the only allowed headword.

Figure 3: Complete parse

Note that $(w_1 \dots w_l)$ *needn't* be a constituent, but for the parses where it is, there is no restriction on which of its words is the headword.

The model will operate by means of two modules:

- **PREDICTOR** predicts the next word w_{k+1} given the word-parse k-prefix and then passes control to the **PARSER**;

- **PARSER** grows the already existing binary branching structure by repeatedly generating the transitions **adjoin-left** or **adjoin-right** until it passes control to the **PREDICTOR** by taking a **null** transition.

The operations performed by the **PARSER** ensure that all possible binary branching parses with all possible headword assignments for the $w_1 \dots w_k$ word sequence can be generated. They are illustrated by Figures 4-6. The following algorithm describes how the model generates a word sequence with a complete parse (see Figures 3-6 for notation):

```

Transition t;           // a PARSER transition
generate <s>;
do{
  predict next_word;    //PREDICTOR
  do{                   //PARSER
    if(T_{-1} != <s> )
      if(h_0 == </s>)   t = adjoin-right;
      else t = {adjoin-left, adjoin-right, null};
    else t = null;
  }while(t != null)
}while(!(h_0 == </s> && T_{-1} == <s>))
t = adjoin-right; // adjoin <s>; DONE

```

It is easy to see that any given word sequence with a possible parse and headword annotation is generated by a unique sequence of model actions.

3 Probabilistic Model

The probability $P(W, T)$ can be broken into:

$$P(W, T) = \prod_{k=1}^{l+1} [P(w_k / W_{k-1} T_{k-1}) \cdot \prod_{i=1}^{N_k} P(t_i^k / w_k, W_{k-1} T_{k-1}, t_1^k \dots t_{i-1}^k)] \text{ where:}$$

- $W_{k-1} T_{k-1}$ is the word-parse $(k-1)$ -prefix
- w_k is the word predicted by **PREDICTOR**
- $N_k - 1$ is the number of adjoin operations the **PARSER** executes before passing control to the **PREDICTOR** (the N_k -th operation at position k is the **null** transition); N_k is a function of T

Figure 4: Before an adjoin operation

Figure 5: Result of adjoin-left

Figure 6: Result of adjoin-right

- t_i^k denotes the i -th **PARSER** operation carried out at position k in the word string;
- $t_i^k \in \{\text{adjoin-left}, \text{adjoin-right}\}, i < N_k$,
- $t_i^k = \text{null}, i = N_k$

Our model is based on two probabilities:

$$P(w_k / W_{k-1} T_{k-1}) \quad (1)$$

$$P(t_i^k / w_k, W_{k-1} T_{k-1}, t_1^k \dots t_{i-1}^k) \quad (2)$$

As can be seen $(w_k, W_{k-1} T_{k-1}, t_1^k \dots t_{i-1}^k)$ is one of the N_k word-parse k-prefixes of $W_k T_k, i = 1, \overline{N_k}$ at position k in the sentence.

To ensure a proper probabilistic model we have to make sure that (1) and (2) are well defined conditional probabilities and that the model halts with probability one. A few provisions need to be taken:

- $P(\text{null} / W_k T_k) = 1$, if $T_{-1} == <s>$ ensures that $<s>$ is adjoined in the last step of the parsing process;

- $P(\text{adjoin-right} / W_k T_k) = 1$, if $h_0 == </s>$ ensures that the headword of a complete parse is $</s>$;

- $\exists \epsilon > 0$ s.t. $P(w_k = </s> / W_{k-1} T_{k-1}) \geq \epsilon, \forall W_{k-1} T_{k-1}$ ensures that the model halts with probability one.

3.1 The first model

The first term (1) can be reduced to an n -gram LM, $P(w_k / W_{k-1} T_{k-1}) = P(w_k / w_{k-1} \dots w_{k-n+1})$.

A simple alternative to this degenerate approach would be to build a model which predicts the next word based on the preceding $p-1$ *exposed headwords* and $n-1$ words in the history, thus making the following equivalence classification:

$$[W_k T_k] = \{h_0 \dots h_{-p+2}, w_{k-1} \dots w_{k-n+1}\}.$$

The approach is similar to the trigger LM(Lau93), the difference being that in the present work triggers are identified using the syntactic structure.

3.2 The second model

Model (2) assigns probability to different binary parses of the word k-prefix by chaining the elementary operations described above. The workings of the PARSER are very similar to those of Spatter (Jelinek94). It can be brought to the full power of Spatter by changing the action of the `adjoin` operation so that it takes into account the terminal/nonterminal labels of the constituent proposed by `adjoin` and it also predicts the nonterminal label of the newly created constituent; PREDICTOR will now predict the next word along with its POS tag. The best equivalence classification of the $W_k T_k$ word-parse k-prefix is yet to be determined. The Collins parser (Collins96) shows that dependency-grammar-like bigram constraints may be the most adequate, so the equivalence classification $[W_k T_k]$ should contain at least $\{h_0, h_{-1}\}$.

4 Preliminary Experiments

Assuming that the correct partial parse is a function of the word prefix, it makes sense to compare the word level perplexity(PP) of a standard n-gram LM with that of the $P(w_k/W_{k-1}T_{k-1})$ model. We developed and evaluated four LMs:

- 2 bigram LMs $P(w_k/W_{k-1}T_{k-1}) = P(w_k/w_{k-1})$ referred to as W and w, respectively; w_{k-1} is the previous (word, POS) pair;
- 2 $P(w_k/W_{k-1}T_{k-1}) = P(w_k/h_0)$ models, referred to as H and h, respectively; h_0 is the previous exposed (headword, POS/non-term tag) pair; the parses used in this model were those assigned manually in the Penn Treebank (Marcus95) after undergoing headword percolation and binarization.

All four LMs predict a word w_k and they were implemented using the Maximum Entropy Modeling Toolkit¹ (Ristad97). The constraint templates in the $\{W, H\}$ models were:

4 $\leq <*>_<*> <?>$; 2 $\leq <?>_<*> <?>$;
 2 $\leq <?>_<?> <?>$; 8 $\leq <*>_<?> <?>$;
 and in the $\{w, h\}$ models they were:

4 $\leq <*>_<*> <?>$; 2 $\leq <?>_<*> <?>$;
 $<*>$ denotes a *don't care* position, $<?>_<?>$ a (word, tag) pair; for example, 4 $\leq <?>_<*> <?>$ will trigger on all ((word, *any tag*), predicted-word) pairs that occur more than 3 times in the training data. The sentence boundary is not included in the PP calculation. Table 1 shows the PP results along with

the number of parameters for each of the 4 models described .

LM	PP	param	LM	PP	param
W	352	208487	w	419	103732
H	292	206540	h	410	102437
